SUBJECT: Rubberband Stiffness Measurement

INTRODUCTION

This memorandum is meant to convey the findings of an experiment conducted to observe the deflection of rubber bands when subjected to a tensile force. The objectives of this experiment are to use force and elongation data to produce a regression model and to use this model to derive a relationship for the elastic energy stored in the rubber bands.

Because Hooke's Law only applies to small ranges of deflection where it is acceptable to assume a linear model, a more accurate model is desirable in order to expand the range in which the force-deflection relationship is known. The proposed model should look somewhat like a standard stress-strain curve, beginning with a steeper slope and then flattening out as the rubber band begins to deform past the elastic range [1]. This behavior refers to the typical true stress-true strain relation known as the "power law." It is expected that the data will follow the power law trend, and the regression model will be fitted to the data as such.

PROCEDURE

The data collected from the test include forces recorded at various steps of the elongation. In the experiment, two rubber bands were connected to a hand-held fish weighing scale. The rubber bands were then stretched to various displacements and the resting force at each length was recorded. A schematic for the experiment can be seen in the included attachments. Four groups carried out the same procedure for eight different lengths and the data was combined to create a larger database.

DATA PRESENTATION & ANALYSIS

The raw data from the experiment can be seen in Figure 1. As predicted, the slope of the data seems to flatten out as the deflections increase in length. A power law regression has been fitted to the data, yielding a correlation coefficient of 0.9608. The Pr range for the regression is much less than 0.1%. The resulting power law regression model can be seen in Equation (1).

$$F = 0.5519x^{0.6253} \quad (1)$$

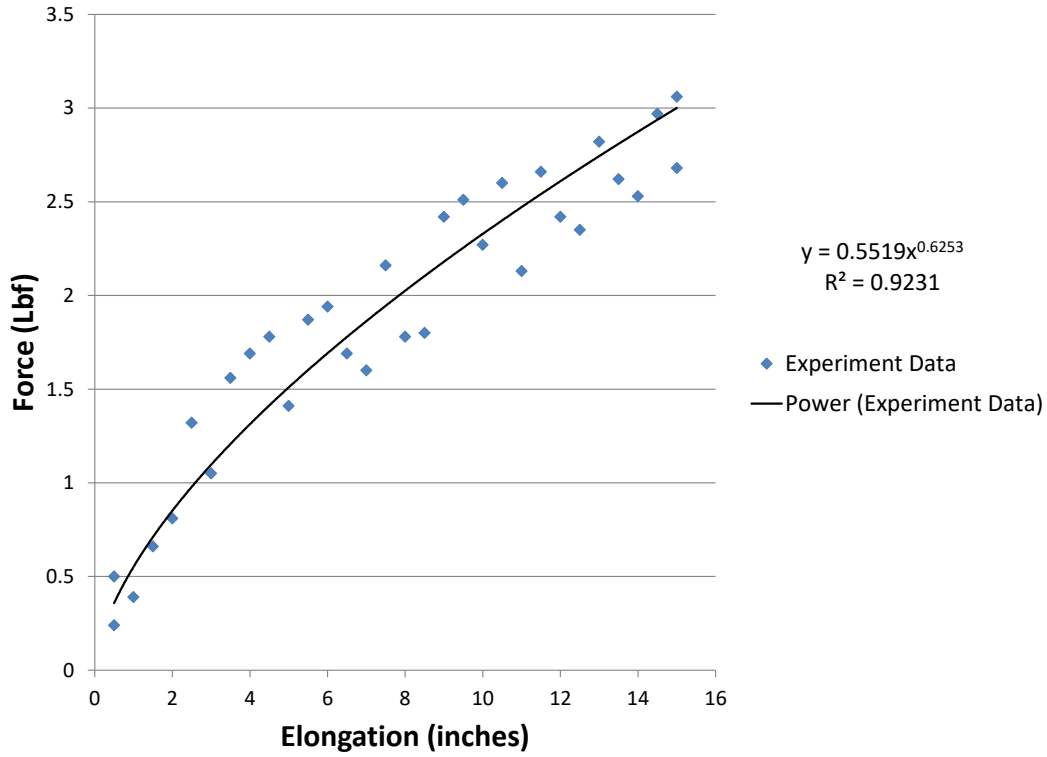

Figure 1: Experiment Data Fitted to Power-Law Regression Model

With a correlation coefficient of 0.9608, it is reasonable to attach a two-way range confidence of 95%. At the mean value of deflections recorded, 7.75 inches, the confidence of estimate interval is found to be 1.986 ± 0.015 . It is expected, due to the scattering of data as elongations get larger, that the range would increase.

In order to derive a relationship for the elastic energy stored in the rubber bands, the regression model was integrated over the length of the displacements using the power rule, shown in Equation (2) and Equation (3). The representation of this relation can be seen in Figure 2.

$$E = \int_0^{\Delta L} F dx \quad (2)$$

$$E = \frac{0.5519x^{1.6253}}{1.6253} \quad (3)$$

DISCUSSION

As expected, the power-law regression model is a good fit for the data since the relation investigated by the experiment is essentially the true-stress true-strain relation, which itself is modeled by a power-law equation.

The data does seem to scatter much more in the upper-range of deflection values. It is likely due to the fact that as the rubber bands are stretched more, their imperfections and variances have a magnified effect on the stress imposed in the band. This means the regression model will lose accuracy as the rubber band is elongated further.

CONCLUSION

- The data from this experiment was fit to a power law regression model.
- The power law regression model fit the data quite well, yielding a correlation coefficient of $R = 0.9608$ and a Pr range of much less than 0.1%, proving that the model should be usable with high confidence of accuracy.

- At the mean value of deflections recorded, the confidence of estimate interval was found to be 1.986 ± 0.015 .
- The regression model was used to derive a relation between the elastic energy stored in the rubber band and the displacement, or elongation, of the rubber band.
